Title: Understanding platelet-rich fibrin / edited by Richard J. Miron.

Description: Batavia, IL : Quintessence Publishing Co Inc, [2021] |

Includes bibliographical references and index. | Summary: "This book outlines the science behind platelet-rich fibrin and then details how to use it in clinical practice to optimize healing outcomes and promote tissue regeneration. Applications include gingival recessions, intrabony and furcation defects, extraction site management, implant dentistry, guided bone regeneration, sinus grafting, oral and maxillofacial surgery, regenerative endodontics, facial esthetics, and medicine"-- Provided by publisher.

Identifiers: LCCN 2020035734 | ISBN 9781647240493 (hardcover)

Subjects: MESH: Platelet-Rich Fibrin | Fibrin--therapeutic use | Tissue Engineering | Bone Regeneration

Classification: LCC QP91 | NLM WH 400 | DDC 612.1/15--dc23

LE PRIX FATIHA CHANDAD

Ce prix fut créé en l'honneur de la Dre Fatiha Chandad, qui a travaillé comme professeure à l'Université Laval pendant plus de trois décennies. Elle a également été vice-doyenne aux études supérieures et à la recherche et directrice du Groupe de recherche en écologie buccale (GREB) au cours des dernières années de sa carrière.

Dre Chandad était une personne lumineuse possédant une passion pour la vie remarquable par son désir d'aider les autres à cheminer. Sa passion pour les sciences combinée à sa volonté à contribuer au développement des élèves, ont été adoptées par des étudiants du monde entier qu'elle a su encadrés au cours de sa carrière. Elle était animée d'une modestie et d'une humilité frappantes; qualités que peu d'individus possèdent dans le monde d'aujourd'hui.

Chaque année, le prix Fatiha Chandad est décerné à un étudiant en quatrième année de médecine dentaire qui a montré des traits de personnalité similaires à ceux du Dr Chandad. Un étudiant qui a su aider d'autres camarades de classe sans motifs personnels et a offert son aide sans réserve dans des situations difficiles ou des périodes de stress lors de leur parcours à la Faculté de Médecine Dentaire.

I would like to dedicate this textbook specifically to Dr Fatiha Chandad and the Dental Faculty at the University of Laval in Quebec, Canada, who devoted countless hours to training students like me in dentistry.

Dr Chandad, Dean of Dental Research, was someone who motivated me and more importantly made it possible for students to work within her laboratory on research projects during their 4 years of dental studies. It was here that I first started my research activities on PRP/PRF and became fascinated with research as a whole. Dr Chandad is one of the only people I have ever met never wanting

to be recognized for her achievements, instead insisting that her students be recognized and at the forefront of their own success. It was during these times that I was awarded the prestigious Hatton Award in Canada and was later named the IADR Young Investigator of the Year in Implant Dentistry.

In appreciation of her contributions to my career, 100% of the royalties from this textbook will be donated to create a scholarship named after her for new dental graduates at the University of Laval. *Milles fois merci pour toutes efforts!*

Foreword

Many important medical/dental discoveries were stumbled upon by pure chance. An example of this is osseointegration, which launched the modern era of dental implants and orthopedic-embedded prostheses. It occurred when orthopedic researcher Per-Ingvar Brånemark found that his titanium research cages in sheep were so completely ingrown with bone that he couldn't remove them. Similarly, platelet-rich plasma (PRP)/platelet-rich fibrin (PRF) was discovered by the serendipity of observing accelerated and more complete healing in patients who developed hematomas. From that simple observation in the 1980s, the components of the blood clot responsible for the advanced healing have since been determined to be the complete and active growth factors in the alpha granules of viable platelets and several cell adhesion molecules and homing signals in the fibrin clot.

From the early pioneering work in the 1990s to the present, the benchmark of platelet numbers and the functional characteristics of the growth factors, cell adhesion molecules, and homing signals of PRP/PRF have progressed to a mature science and easy-to-use point-of-care devices.

Today, PRP/PRF devices are able to predictably concentrate platelets to known therapeutic levels by a variety of technologic means and to include or exclude leukocytes as per the needs of the wound. PRP/PRF has become a

mainstay in bone regeneration in dental implantology and jaw reconstruction, for tendon and joint repair in orthopedics, for soft tissue healing in wound care centers, and in plastic surgery; it has thus benefited hundreds of thousands of patients worldwide.

As one of several individuals who were there at the beginning of the PRP/PRF discovery and who helped to move it along the way somewhat, I am delighted to see that the next generation of clinical researchers as published in *Understanding Platelet-Rich Fibrin* have brought it to the next level.

This text is written for the clinician to understand how and why PRF promotes healing of both bone and soft tissue as well as how to apply it to improve their own results. Written with a balanced blend of science and clinical applications by the most experienced and accomplished PRP/PRF scientists and clinicians of the day, and beautifully illustrated, *Understanding Platelet-Rich Fibrin* is a book for this decade that transcends all specialties of dentistry and many of medicine.

Robert E. Marx, DDS
Professor of Surgery and Chief of OMFS
University of Miami
Miller School of Medicine
Miami, Florida

Preface

Over 20 years ago, platelet concentrates entered into the medical field as a means to deliver autologous growth factors responsible for favoring wound healing. During this time span, it has gained widespread acceptance in many fields of medicine due to its more natural delivery system.

Most notably, the past 5 years have seen a tremendous increase in publications on PRF, with over 200 scientific peer-reviewed papers being published each and every year. During this span, a marked increase in our understanding of PRF therapy has been made with respect to selection of appropriate centrifugation devices, impact of tube chemistry on clotting, the optimization of protocols to better concentrate PRF, and even the ability to extend the working properties of PRF from 2–3 weeks toward 4–6 months using a simple heating process. Collectively, we continue to gather new knowledge, and as a result, PRF therapy has become one of the fastest-growing therapeutic options in dentistry. Thousands of users have now benefited from this technology, and this number is only expected to continue to increase.

This book is very different from others in its concept design. More than a dozen expert researchers and clinicians

alike were gathered as editors across their different fields of expertise. As section editors, these true experts of their respective disciplines were able to produce a much higher overall quality of this textbook. I am grateful for their encouraging team spirit, their effort in bringing this book to an entirely new level, and their level of professionalism and mindset that ultimately led to this comprehensive textbook. I am also grateful to the numerous clinicians who have provided videos to better educate/demonstrate surgical techniques and concepts with PRF, which will greatly enhance the learning experience of the reader.

The book is divided into four primary sections, including (1) biology of PRF, (2) periodontology, (3) implant dentistry, and (4) additional dental and medical applications. The book aims to take the reader from a basic biologic understanding of PRF through explanations of the various protocols utilized followed by application of these concepts in numerous clinical scenarios.

I therefore am thrilled to introduce our textbook titled *Understanding Platelet-Rich Fibrin*. I hope you enjoy learning the many aspects centered around the use of PRF in regenerative dentistry.

Acknowledgments

To my parents, family, and friends who have all sacrificed far too often in my pursuit of a career in academic dentistry.

To my classmates, colleagues, and mentors who constantly raised the bar and strived for better.

To Quintessence Publishing for your thorough input in the editing, illustrations, and design of this textbook.

To my family at Lakewood Ranch Dental in Florida who have made clinical practice as enjoyable an experience as can be on a *daily* basis.

To all leaders and researchers alike who have contributed enormously to the field of PRP/PRF and laid the foundation for this textbook to be written.

To the faculty in the Department of Biomedical Sciences and Cell Biology at the University of Western Ontario

(London, Canada; BMSc, MSc), the Dental School at the University of Laval (Quebec; DDS), the Department of Music at Berklee College (Boston; MMus), the Department of Periodontology at the University of Bern (PhD, Dr med dent), the Department of Oral Implantology at Wuhan University (China; postdoctoral research fellow), the Plastic Surgery Department at Queen Mary University (London; clinical masters in facial esthetics), and the Department of Periodontology at the University of Illinois at Chicago (clinical masters in periodontology). Your education and mentorship has provided endless opportunities.

And lastly, to the team at Advanced PRF Education (www.prfedu.com) for making excellence in teaching a top priority.

KTW	keratinized tissue width	WBC	white blood cell

Evolution of Platelet Concentrates

Platelet concentrates were derived more than 20 years ago following the discovery that platelets themselves act as key regulators during the wound healing process. Initial attempts were first made to concentrate these cells using anticoagulants and a centrifugation device; the resulting biomaterial was called *platelet-rich plasma* (PRP). Shortly thereafter, protocols were developed with the aim of avoiding the use of anticoagulants altogether, because clotting is a pivotal step during the wound healing cascade; the resulting biomaterial was called *platelet-rich fibrin* (PRF). Today, platelet concentrates have become incredibly relevant worldwide, with their use spanning across nearly every field of regenerative medicine. Furthermore, one of the main growth factors (GFs) found in platelets—platelet-derived growth factor (PDGF)—has been commercialized as a ready-made laboratory recombinant protein under the trade name GEM 21S (Lynch Biologics). Thus, as medicine has continued to evolve and progress, an obvious and clear trend favoring GF use has been established. Furthermore, by modifying centrifugation devices and spin protocols of PRP/PRF, a greater ability to concentrate not only platelets but also leukocytes became possible, further favoring tissue regeneration. This chapter takes a deep look at the years of research leading to the significant advancement that has been made in this field. The evolution from PRP to PRF, including pioneering concepts such as the low-speed centrifugation concept and horizontal centrifugation, are discussed in terms of their ability to favor higher cell content, GF concentration, and ultimately better wound healing.

Contributors

Richard J. Miron

Chapter Highlights

- Evolution of PRF and the reasons for its discovery
- Discussion of PRP vs PRGF vs PRF vs L-PRF, A-PRF, etc
- Biologic background of key steps involved during wound healing

Video 1-1

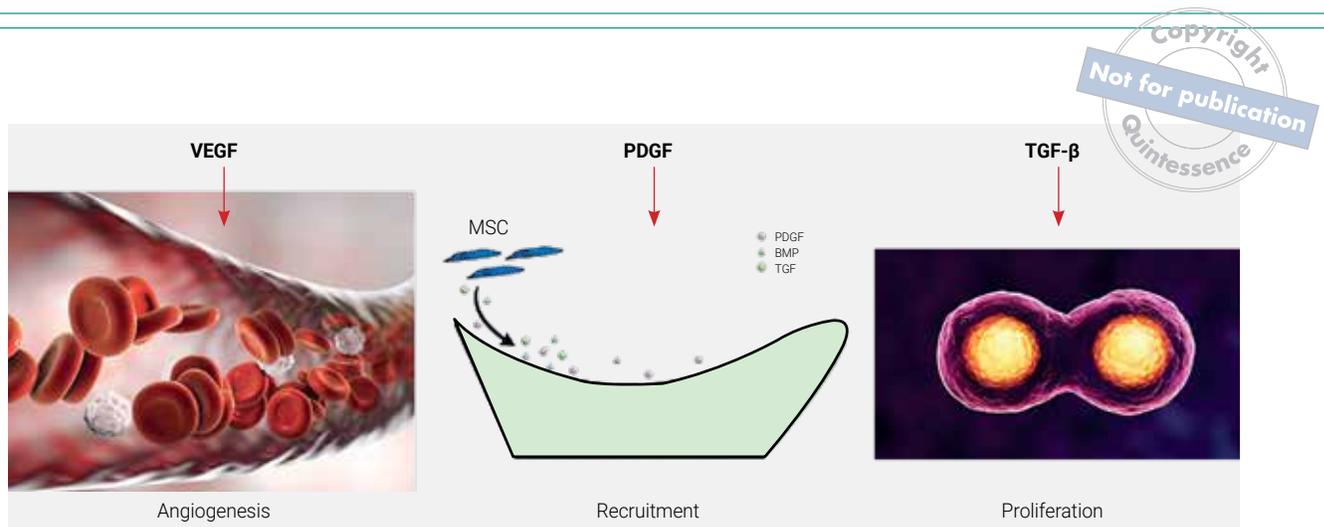

Fig 1-1 The three main GFs that are released from PRF include VEGF, a known inducer of angiogenesis; PDGF, a known inducer of cell recruitment; and TGF- β 1, a known stimulator of cell proliferation. MSC, mesenchymal stem cell.

Platelet concentrates have been utilized in medicine for over two decades because of their ability to rapidly secrete autologous GFs and ultimately speed wound healing. They have gained tremendous momentum as a regenerative agent derived from autologous sources capable of stimulating tissue regeneration in a number of medical fields.^{1,2} Many years ago, it was proposed that by concentrating platelets using a centrifugation device, GFs derived from blood could be collected from a platelet-rich plasma layer and later utilized in surgical sites to promote local wound healing.^{1,2} Today, it has been well established that platelet concentrates act as a potent mitogen capable of the following (Fig 1-1):

- Speeding the revascularization of tissues (angiogenesis)
- Recruiting various cells including stem cells
- Inducing the prompt multiplication of various cell types found in the human body (proliferation)

Wound healing is a complex biologic process whereby many cell types interact with one another as well as their local extracellular matrix (ECM) in order to repair and regenerate damaged tissues.³⁻⁶ While many regenerative agents currently exist on the market to help speed tissue regeneration, it is important to note that the majority are derived from other human sources (allografts) and animal byproducts. These naturally create a foreign body reaction when implanted into host tissues. While the majority of such biomaterials do certainly favor improved healing, it has generally been recognized and accepted that the gold standard for the

majority of tissue-regenerative procedures in basically every field of medicine has been the use of autogenous tissues.

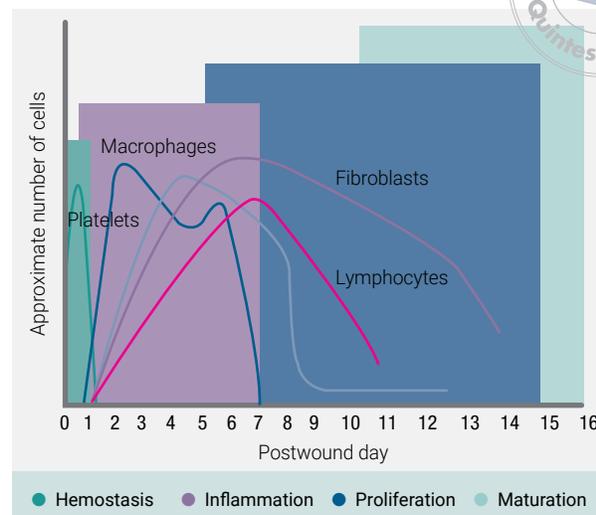

Specifically in dentistry, platelet concentrates were introduced over 20 years ago by Robert E. Marx and colleagues with the aim of concentrating blood proteins as a natural source of GFs that would stimulate vascularization (angiogenesis) and tissue ingrowth based on the fact that blood supply is pivotal for tissue regeneration of all tissues.⁷ Wound healing has been described as a four-step process that includes (1) hemostasis, (2) inflammation, (3) proliferation, and (4) maturation⁸⁻¹⁰ (Fig 1-2). Each phase overlaps one another and encompasses various microenvironments, including different cell types that assist in wound healing. Noteworthy are the implications of immune cells during biomaterial integration. In a study titled "OsteoMacs: Key players around bone biomaterials," osteal macrophages were discussed as being key and pivotal cells during the wound healing process.¹¹ Thus, as tissue biology has continued to evolve, platelet concentrates have also seen significant advancement with respect to their ability to favor healing by incorporating immune cells (leukocytes). Various systematic reviews from multiple fields of medicine have now demonstrated their ability to support tissue regeneration across many tissue types and cell types. This chapter reviews the evolution of platelet concentrates.

PRP (1990s)

The use of platelet concentrates has slowly and gradually gained popularity over time, with a dramatic increase

Fig 1-2 Four phases of wound healing: (1) hemostasis, (2) inflammation, (3) proliferation, and (4) maturation. Noteworthy are the overlaps between each of the phases and the population of cells found in each category. Whereas lymphocytes typically arise at 7 days, the ability of PRF to introduce a high number at day 0 acts to speed the regenerative phase during this process.

being observed in the past 5 to 10 years. This parallels precisely the massive increase in research articles being published on the topic. Despite this, it is important to review and highlight the pioneering work conducted by Marx and colleagues over 20 years ago, without which none of this textbook would exist.¹²⁻¹⁴

Platelet-rich plasma (PRP), as its name implies, was designed to accumulate platelets in supraphysiologic doses within the plasma layer following centrifugation. The main aim of PRP was to isolate and further concentrate the highest quantity of platelets and their associated GFs for regenerative purposes, thereafter reimplanting this specialized supraconcentrate at sites of local injury. This concept has been the basis of thousands of research articles, with their protocols being utilized to favor wound healing in millions of patients.

Initial protocols typically ranged in duration from 30 minutes to 1 hour based on the centrifugation/collection systems and protocols utilized. The original concept was pioneered by Harvest Technology, where it was shown that over 95% platelet concentration could be accumulated, having the potential to help favor the regenerative phase of many cell types including soft tissues, epithelial cells, periodontal ligament cells, and bone cells.^{15,16} Because these initial protocols were lengthy, anticoagulants were added to the blood collection tubes. These typically were various forms of concentrated bovine thrombin or sodium citrate.

Despite its growing success and continued use after its discovery, several reported limitations existed with these initial formulations of PRP. The 30-minute or longer technique

was generally considered lengthy for routine dental or medical practice, and more importantly, the use of anticoagulants was shown to limit wound healing from reaching its maximum potential. Simply put, when injury is created following an open wound, a blood clot is one of the first steps that occurs in order for healing to take place. Shortly thereafter, cells and GFs get trapped within this newly formed ECM, and the wound healing process/cascade begins. By limiting the body's ability to form a stable clot, wound healing is limited. Several studies have now demonstrated the superior outcomes of platelet-rich fibrin (PRF) when compared to PRP simply by removing anticoagulants from their formulations.¹⁷⁻²¹ Even the pioneering research team behind the plasma rich in growth factors (PRGF) concept (Anitua et al) have since demonstrated more physiologic healing ability with anticoagulant removal.¹⁷

Another drawback of PRP was the fact that it remained liquid by nature (due to the use of anticoagulants), so when it was combined with biomaterials, a much faster delivery of GFs was observed (Fig 1-3). While an initial burst of GFs is typical of PRP therapy, a slower release of GFs over an extended period of time has been shown to better stimulate cell growth and tissue regeneration.^{22,23}

Much advancement related to PRP therapy has been made over the past 20 years, and two excellent textbooks have been written by its pioneers—*Dental and Craniofacial Applications of Platelet-Rich Plasma* by Robert E. Marx and Arun K. Garg (Quintessence, 2005), and *Autologous Blood Concentrates* by Arun K. Garg (2018). Its breakthrough features include the novel ability to concentrate platelets

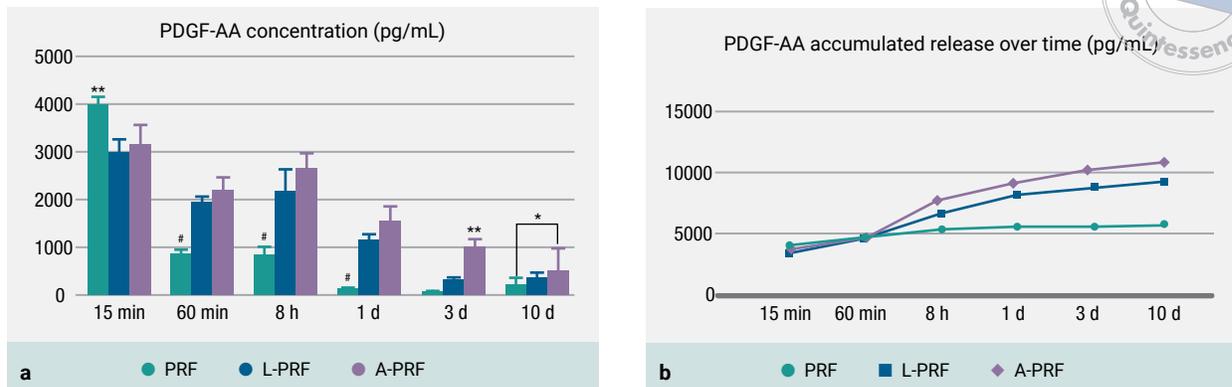

Fig 1-3 (a and b) GF release from PRP and PRF at each time point of PDGF-AA over a 10-day period. Notice that while PRP has significantly higher GF release at early time points, over a 10-day period, significantly higher levels are most commonly found with A-PRF due to the slow and gradual release of GFs utilizing slower centrifugation speeds. (Adapted from Kobayashi et al.¹⁹)

to supraphysiologic doses and further stimulate tissue regeneration across virtually all tissue types. For these reasons, PRP has not surprisingly been utilized in practically every field of medicine.

Snapshot of PRP

- Marx was the first to show that a concentration of platelets could favor tissue regeneration in the oral cavity.
- A subsequent device was brought to market thanks to these breakthrough research projects conducted at the University of Miami (Harvest system).
- PRP is credited for having exponentially grown the entire field of platelet concentrates, including its subcategories such as PRF.

L-PRF (2000–2010)

Because the anticoagulants utilized in PRP prevented clotting, pioneering work performed by Dr Joseph Choukroun and Dr David Dohan Ehrenfest led to the development of PRF.²⁴ The aim was to develop a second-generation platelet concentrate focused on anticoagulant removal. Because anticoagulants were removed, a much quicker working time was needed, and centrifugation had to begin shortly after blood draw (otherwise, the blood would naturally clot). Furthermore, high g-force centrifugation protocols were initially utilized in an attempt to separate blood layers prior

to clotting. The final spin cycle (initial studies ranged from 2500–3000 rpm for 10–12 minutes = ~700g) resulted in a plasma layer composed of a fibrin clot with entrapment of platelets and leukocytes. The main advantage of this fibrin matrix was its ability to release GFs over an extended period of time while the fibrin clot was being degraded.²⁵ Over the years, PRF has been termed *L-PRF* (for *leukocyte platelet-rich fibrin*) due to the discoveries that several leukocytes remained incorporated in PRF and that white blood cells play a central and key role in the tissue healing process. The most commonly utilized protocol today is a spin cycle at 3000 rpm for 10 minutes or 2700 rpm for 12 minutes (RCF-max = ~700g, RCF-clot = ~400g).

Several other advantages also existed during clinical use because it avoided the need for dual-spin protocols requiring pipetting or various specialized tube compartments, which made the overall procedure much more user-friendly, cheaper, and faster when compared to PRP. Original protocols were purposefully designed to spin at high centrifugation speeds with the main aim of phase separation to occur as quickly as possible in order to separate the red corpuscle base layer from the upper plasma layer prior to clotting. Following centrifugation, a platelet-rich fibrin mesh was formed, giving it the working name *PRF*^{26–28} (Fig 1-4). PRF has since been highly researched, with over 1,000 publications dedicated to this topic alone.

Additionally, research teams from around the world have demonstrated the impact of leukocytes on tissue healing.^{29–34} While it was once thought that the additional benefit of leukocyte incorporation into PRF was its main properties in improved host defense to foreign pathogens,^{29–34} it has since been shown in well-conducted basic research studies

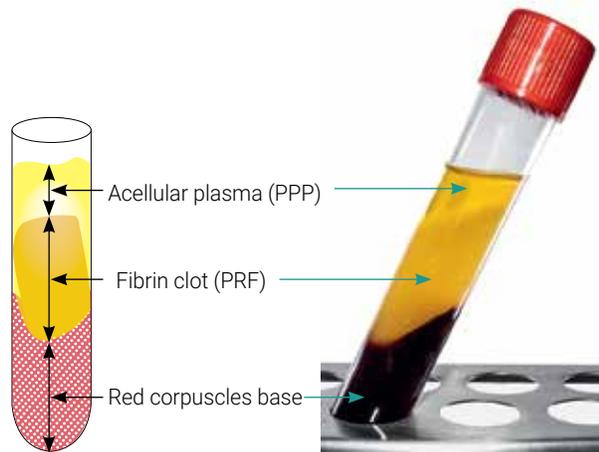

Fig 1-4 Layers produced after centrifugation of whole blood. A PRF clot forms in the upper portion of tubes after centrifugation.

that leukocytes are pivotal to tissue regeneration and favor faster wound healing also.^{11,35–37} In dentistry, where the oral cavity is filled with bacteria and microbes, the inclusion of leukocytes was initially thought to play a pivotal role in wound healing by participating in the phagocytosis of debris, microbes, and necrotic tissues, as well as directing the future regeneration of these tissues through the release of several cytokines and GFs and orchestrating cell-to-cell communication between many cell types.

Tissue engineering with PRF

Tissue engineering has been an emerging discipline over the past decade, with major breakthroughs routinely being made every year. At its simplest foundation, tissue engineering requires three parameters: (1) a scaffold responsible to support tissue ingrowth, (2) cells that may act to promote tissue regeneration, and (3) GFs that stimulate the overall wound healing events. Unlike the majority of biomaterials currently available on the market, PRF actually contains each of these three properties (Fig 1-5). For comparative purposes, routine bone allografts contain a scaffold (mineralized cortical/cancellous bone) and GFs embedded in its bone matrix (such as bone morphogenetic protein 2 [BMP-2]) but have no cells. Recombinant human GFs typically have a GF (for instance, rhBMP-2) and a carrier (collagen sponge) but also lack cells. Certain stem technologies typically contain cells and also a delivery

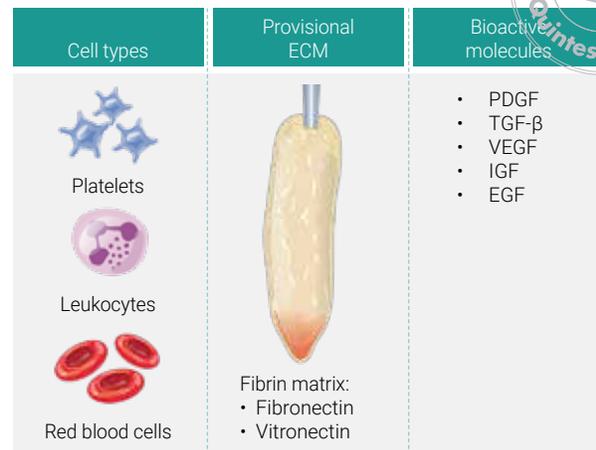

Fig 1-5 Three main components of PRF all derived naturally from the human body. These include (1) cell types (platelets, leukocytes, and red blood cells); (2) a provisional ECM 3D scaffold fabricated from autologous fibrin (including fibronectin and vitronectin); and (3) a wide array of over 100 bioactive molecules, including most notably PDGF, TGF- β , VEGF, IGF, and EGF.

system (for instance a nanocarrier delivery system) but lack GFs. The ability to actually contain each of the three tissue engineering properties within a single biomaterial is quite rare and, more importantly, usually extremely expensive (think recombinant GFs and/or stem cell technology).

PRF, on the other hand, is a particularly simple and inexpensive way to utilize the three principles of tissue engineering by utilizing a 3D scaffold (fibrin) that incorporates both regenerative host cells (platelets and leukocytes) and various GFs. These include PDGF, TGF- β , and VEGF, each of which is crucial during the regeneration process. Furthermore, the concentrated leukocytes (as opposed to simply platelets) in PRF have been well implicated as key regulators of tissue healing and formation.^{26–28,31,38}

Snapshot of PRF

- PRF is considered a second-generation platelet concentrate with a longer GF release profile.
- Centrifugation protocols are shorter and do not need any chemical additives such as anticoagulants.
- PRF falls more in line with tissue engineering principles in that it is not only an accumulation of cells and GFs but also a scaffold (fibrin matrix).
- PRF incorporates leukocytes, which are key cells in pathogen defense and biomaterial integration.

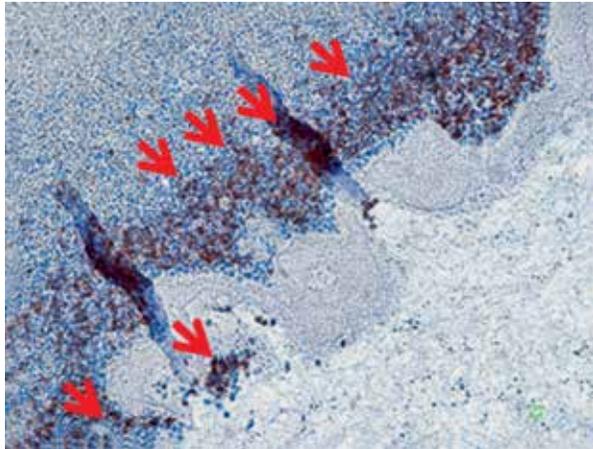

Fig 1-6 Histologic observation of leukocytes following centrifugation. Resulting white blood cells have been shown to be contained basically in the layers between the plasma PRF layer and the red blood cell clot. This finding demonstrated quite clearly that the g-force was excessive, necessitating the development of newer protocols aimed to improve the retention of leukocytes within the PRF matrix. (Reprinted with permission from Ghanaati et al.³⁹)

A-PRF and i-PRF (2014–2018)

While much of the research performed in the late 2000s and early 2010s was dedicated to the clinical uses and indications of L-PRF discussed later in this textbook, major discoveries were made several years later from basic research laboratories. Following extensive clinical use and research with the original L-PRF protocol, it was discovered in 2014 by Dr Shahram Ghanaati that centrifugation carried out at relatively high centrifugation speeds ($\sim 700g$) led to the great majority of leukocytes being located either at the buffy coat zone (between the red blood cell layer and the upper plasma layer) or more commonly at the bottom of centrifugation tubes (Fig 1-6).³⁹ It was expressed that the longer the centrifugation time is carried out, the more likely it is that cells get pushed further down the centrifugation tube. Similarly, the faster the spin centrifugation speed (higher g-force), the greater the proportion of cells found in the lower levels of centrifugation tubes.

Pioneering research within his laboratory led to the development of an advanced PRF (A-PRF) whereby lower centrifugation speeds ($\sim 200g$) led to a higher accumulation of platelets and leukocytes more evenly distributed throughout the upper PRF layers. These newer protocols more favorably led to a higher release and concentration of GFs over a 10-day period when compared to PRP or L-PRF.¹⁹ In 2015 to 2017, our research team further demonstrated that optimization of PRF

Fig 1-7 Newer centrifugation protocols allow production of a liquid formulation of PRF found in the top 1- to 2-mL layer of centrifugation tubes following a 3- to 5-minute protocol. This liquid can be collected in a syringe and reinjected into defect sites or mixed with biomaterials to improve their bioactive properties. (Reprinted with permission from Davies and Miron.⁴⁰)

could be achieved by reducing not only centrifugation speed but also the time involved. The A-PRF protocol was therefore modified from 14 minutes at 200g as originally described in 2014 down to an 8-minute protocol.¹⁹

Following an array of basic research studies on this topic, it was observed that by further reducing the g-force and also the time, it was possible to obtain a plasma layer that had not yet converted into fibrin (ie, scientifically liquid fibrinogen but often referred to as *liquid-PRF* for simplicity). In a study titled “Injectable platelet rich fibrin (i-PRF): Opportunities in regenerative dentistry?”,²⁰ it was demonstrated that at lower centrifugation speeds and times ($\sim 60g$ for 3 minutes), a liquid-PRF (termed *injectable-PRF* or *i-PRF*) could be obtained. While these protocols typically produced minimal volumes (~ 1.0 – 1.5 mL), it was shown that both platelets and leukocytes were even more highly concentrated when compared to L-PRF or A-PRF (Fig 1-7).⁴⁰ This liquid-PRF layer could be utilized clinically for approximately 15 to 20 minutes, during which time fibrinogen and thrombin had not yet converted to a fibrin matrix (ie, remained liquid). This has since been utilized for injection into various joints/spaces similar to PRP, however with the reported advantages of a longer GF release time. Furthermore, the concept of “sticky” bone was also developed. Importantly, a different type of tube (plastic) was needed to minimize clotting, as will be discussed in detail in chapter 5.

a

b

Fig 1-8 (a) Clinical photograph of a Bio-PRF centrifuge. (b) Photograph demonstrating the horizontal centrifugation concept. The tubes are inserted vertically (up and down), but once the device begins to rotate, the tubes swing out completely horizontally. This favors better blood cell layer separation with higher platelet and GF concentrations.

Snapshot of A-PRF and i-PRF

- Original L-PRF protocols were shown to be too fast, leading to all the cells being accumulated only at the buffy coat zone, with the majority of leukocytes found within the red blood cell layer.
- The low-speed centrifugation concept was shown in 2014 to favor a higher concentration of cells within PRF membranes.
- By further lowering speed and time, a liquid-PRF formulation became available, commonly known as *injectable-PRF* (or i-PRF).

Video 1-2

see also chapters 2 and 3). Unlike fixed-angle centrifugation systems whereby the tubes are actually inserted at a 45-degree angle, in horizontal centrifugation systems (often referred to as *swing-out bucket centrifugation*), the tubes have the ability to swing out to 90 degrees once they are in rotation (Video 1-2). Amazingly, the original PRP systems developed by Harvest and Marx utilized and still use this technology.

H-PRF and C-PRF (2019–Present)

Very recently, our research group discovered through a series of basic laboratory experiments that horizontal centrifugation led to significantly greater concentrations of platelets and leukocytes when compared to currently available fixed-angle centrifugation devices most commonly utilized to produce L-PRF and A-PRF. Simply, horizontal centrifuges are routinely utilized in high-end research laboratories as well as in medical hospitals because of their greater ability to separate layers based on density (Fig 1-8;

In 2019, an article on the topic demonstrated clearly that horizontal centrifugation could lead to up to a four-times greater cell content when compared to fixed-angle centrifugation.⁴¹ This represented a marked ability to greatly concentrate cells found within PRF, which were primarily being accumulated on the back distal surfaces of PRF tubes (Fig 1-9). The major disadvantage of fixed-angle centrifugation is that during the spin cycle, cells are typically driven along the back wall of the centrifugation tubes at high g-forces (Fig 1-10). This also exposes cells to higher compressive forces against the back wall, and

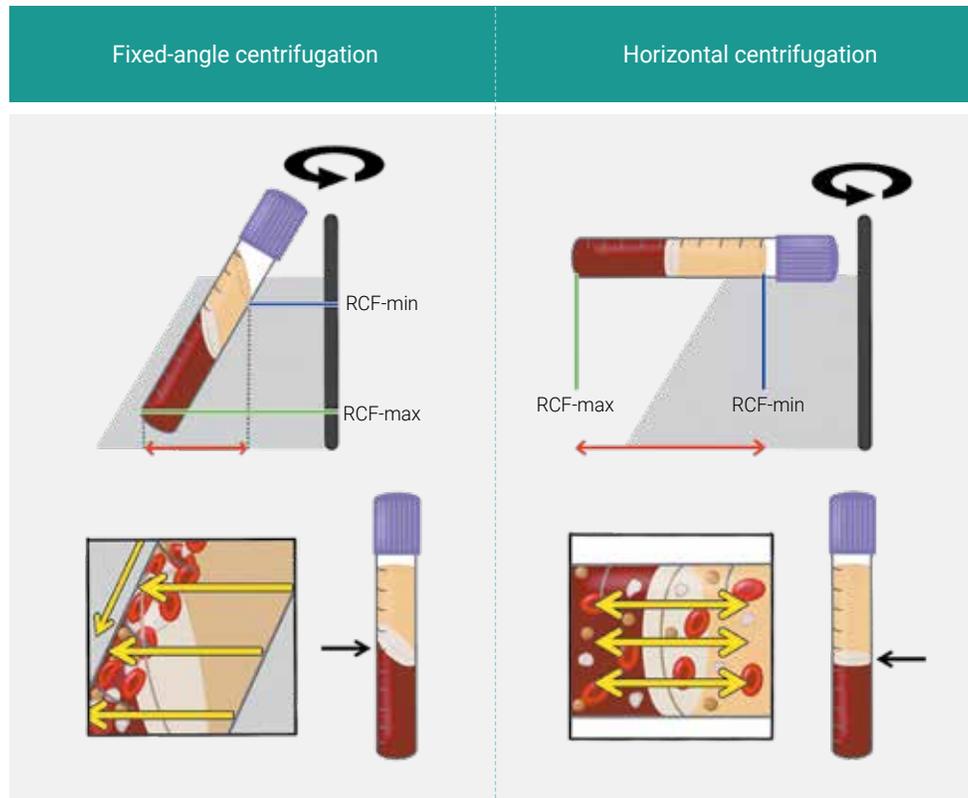

Fig 1-9 Illustrations comparing fixed-angle and horizontal centrifuges. With horizontal centrifugation, a greater separation of blood layers based on density is achieved owing to the greater difference in RCF-min and RCF-max. Following centrifugation on fixed-angle centrifuges, blood layers do not separate evenly, and as a result, an angled blood separation is observed. In contrast, horizontal centrifugation produces even separation. Owing to the large RCF values ($\sim 200g$ – $700g$), the cells are pushed toward the outside and downward. On a fixed-angle centrifuge, cells are pushed toward the back of centrifugation tubes and then downward/upward based on cell density. These g-forces produce additional shear stress on cells as they separate based on density along the back walls of centrifugation tubes. In contrast, horizontal centrifugation allows for the free movement of cells to separate into their appropriate layers based on density, allowing for better cell separation as well as less trauma/shear stress on cells. (Modified from Miron et al.⁴¹)

cells must then separate by traveling either up or down the inclined centrifugation slope based on their respective cell density differences. Because red blood cells are larger and heavier than platelets and leukocytes, they travel downward, whereas lighter platelets travel toward the top of the tube where PRF is collected. This makes it relatively difficult for the small cell types such as platelets and leukocytes to reach the upper layer, especially granted that red blood cells outnumber in particular white blood cells typically by 1,000-fold (see chapter 2). Therefore, it is not possible to reach optimal accumulation of platelets or leukocytes using a fixed-angle centrifuge.

Furthermore, by utilizing a novel method to quantify cell types found in PRF, it was possible to substantially

improve standard i-PRF protocols that favored only a 1.5- to 3-fold increase in platelets and leukocytes. Noteworthy is that several research groups began to show that the final concentration of platelets was only marginally improved in i-PRF when compared to standard baseline values of whole blood.^{41,42} In addition, significant modifications to PRF centrifugation protocols have further been developed, demonstrating the ability to improve standard i-PRF protocols toward liquid formulations that are significantly more concentrated (C-PRF) with over 10- to 15-times greater concentrations of platelets and leukocytes when compared to i-PRF (see chapters 2 and 3). Today, C-PRF has been established as the most highly concentrated PRF protocol described in the literature.

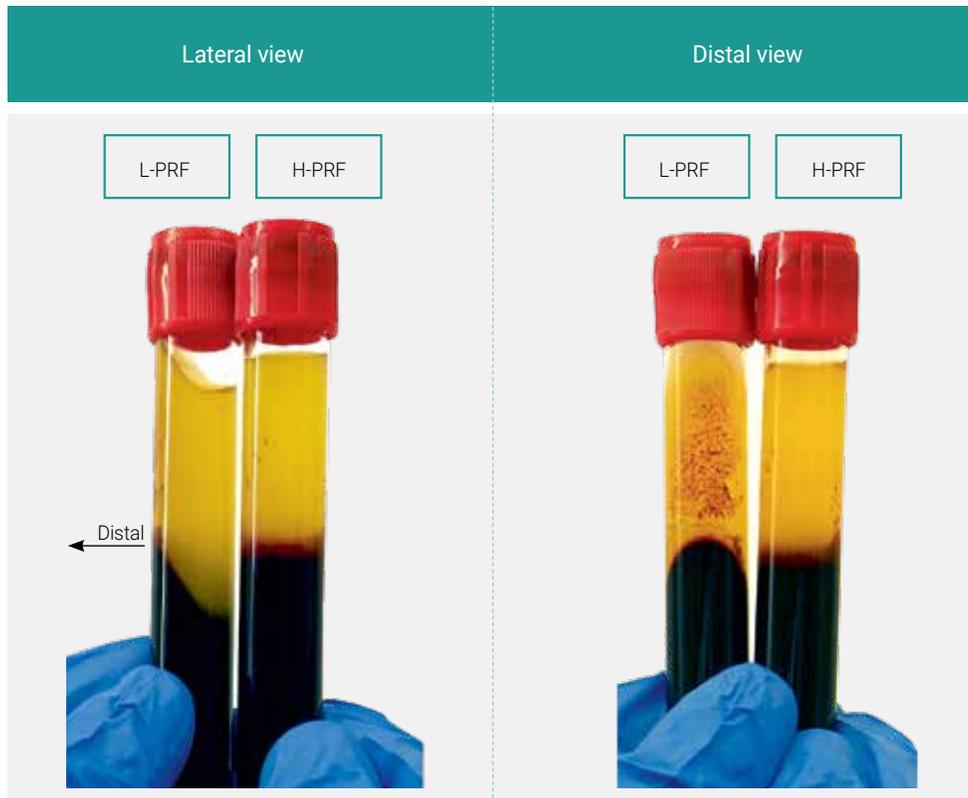

Fig 1-10 Visual representation of layer separation following either L-PRF or H-PRF protocols. L-PRF clots are prepared with a sloped shape, and multiple red dots are often observed on the distal surface of PRF tubes, while H-PRF results in horizontal layer separation between the upper plasma and lower red corpuscle layer.

Snapshot of H-PRF and C-PRF

- Horizontal centrifugation leads to up to a four-times greater accumulation of platelets and leukocytes when compared to fixed-angle centrifugation systems commonly utilized to produce L-PRF and A-PRF.
- Cells accumulate evenly when PRF is produced via horizontal centrifugation as opposed to along the back distal surface of PRF tubes on fixed-angle centrifuges.
- Standard i-PRF can be further improved with horizontal centrifugation.

Conclusion

Platelet concentrates have seen a wide and steady increase in popularity since they were launched more than two decades ago. While initial concepts launched in the 1990s led to the working name *platelet-rich plasma*, subsequent years and discoveries have focused more specifically on their anticoagulant removal (ie, PRF). Several recent improvements in centrifugation protocols, including the low-speed centrifugation concept and horizontal centrifugation, have led to increased concentrations of GFs and better healing potential. Both solid-PRF as well as liquid-based formulations now exist, with an array of clinical possibilities created based on the ability to accumulate supraphysiologic doses of platelets and blood-derived GFs. Future strategies to further improve PRF formulations and protocols are continuously being investigated to additionally improve clinical practice utilizing this technology.
